INTRODUCTION

A critical need exists for efficient, measurable systems of disease management that reconcile conflicts between socioeconomic responsibility and patient welfare. Clinical guidelines have become an important component of these systems because they address elements of care that are effective and that reduce the variability in our approach to patient management.

The American Association of Clinical Endocrinologists (AACE) 2001 Medical Guidelines for Clinical Practice for the Prevention and Management of Postmenopausal Osteoporosis address the prevention, diagnosis, and management of postmenopausal osteoporosis, a disorder that is recognized as a major public health problem because of its physical and socioeconomic consequences. They are intended to simplify medical decision making and to help physicians and their patients make good decisions about skeletal health and postmenopausal osteoporosis.

The specific goals of these guidelines are to reduce the incidence of fractures related to osteoporosis and to achieve the highest quality of life for individual patients by using the most effective and efficient methods of diagnosis and management.

In the preparation of this 2001 edition, reports in the peer-reviewed literature dealing with prevention, diagnosis, and treatment of postmenopausal osteoporosis, which were published and indexed between 1996 (the publication date of the previous edition of these guidelines) and January 2001, were identified by computer search, reviewed, and graded for clinical relevance and scientific merit. Although cost-effectiveness was carefully considered, variabilities in actual costs could not be accurately determined. Therefore, cost-effectiveness modeling was not undertaken.

Whenever possible, recommendations were based on randomized, prospective, double-blind studies of well-defined patient populations. Studies that used the most relevant clinical endpoint, fracturing, were considered “level 1” evidence. When level 1 evidence was not available, recommendations were based on cross-sectional studies, investigations that tested smaller or nonrandomized patient populations, or studies that tested secondary or surrogate clinical endpoints for fracture, such as bone mineral density (BMD) or bone turnover markers, in treated populations (level 2 evidence). When stronger evidence was not available, reviews, editorials, and expert opinions were used (level 3 evidence).

We recognize that the process of developing clinical guidelines necessarily results in a narrowing and codification of clinical choices, which can be inappropriate in some clinical situations. Because the application of objective information to the specific needs of patients is the ultimate responsibility of the practicing physician, clinical practice guidelines are not intended to be rigid or restrictive, nor should they be used for the formation of public policy.

As a basic principle of medical decision making, AACE also recognizes a physician’s prerogative to refer the patient for consultation to qualified experts. Osteoporosis is a complex endocrinologic disorder of bone and mineral metabolism. Formal training in the science and clinical management of metabolic bone disease is a basic element of the endocrinologist’s academic preparation. Therefore, the clinical endocrinologist is a reliable resource for primary physicians who seek consultation for their patients with osteoporosis and other metabolic bone diseases and for patients who desire subspecialty care.

Referral to an osteoporosis specialist is appropriate when the patient is in any of the following circumstances:

1. Has osteoporosis that is unexpectedly severe or has unusual features at the time of initial assessment
   • Has very low BMD (a T-score below −3.0 or a Z-score below −2.0)
   • Has osteoporosis despite young age (premenopausal)
   • Has fractures despite borderline or normal BMD
2. Has a suspected or known condition that may underlie the osteoporosis (for example, hyperthyroidism, hyperparathyroidism, hypercalciuria, Cushing’s syndrome, or hypogonadism)
3. Is a candidate for combination therapy
4. Is intolerant of approved therapies
5. Fails to respond to treatment
   • Takes estrogen yet has low baseline BMD
   • Is undergoing treatment yet shows an apparent loss of BMD on serial studies
   • Has fractures despite treatment
POSTMENOPAUSAL OSTEOPOROSIS:
DEFINITION

Postmenopausal osteoporosis is a condition characterized by the following features:

- Low bone mass
- Microarchitectural deterioration of bone tissue, leading to bone fragility
- A consequent susceptibility to fracture

Osteoporosis-related fractures may lead to diminished quality of life, disability, and even death.

The World Health Organization (WHO) has established an operational definition of osteoporosis based on BMD, commonly expressed as a T-score (Table 1). A T-score represents a patient’s bone density expressed as the number of standard deviations (SDs) above or below the mean BMD value for a normal young adult.

Although the WHO criteria were not intended as references for making treatment decisions, they may be used for this purpose. The WHO criteria are also useful for making public health and health policy decisions for populations of patients for whom no specific clinical information is available. In addition, the WHO BMD criteria are commonly accepted as standards for research purposes.

BACKGROUND

- Postmenopausal osteoporosis affects many people. Although white women are most often affected, women of all races and all ethnic origins are susceptible to osteoporosis and fracture. Men and younger women may also have osteoporosis; however, these guidelines are limited to postmenopausal osteoporosis.
- By the end of the first postmenopausal decade, half of white women have osteopenia or osteoporosis (Fig. 1).
- Low BMD at the femoral neck (T-score of −2.5 or below) is found in 21% of postmenopausal white American women, 16% of postmenopausal Mexican American women, and 10% of postmenopausal African American women.
- The prevalence of vertebral fractures among postmenopausal women is higher than 20%.
- Less than one-third of the cases of osteoporosis have been diagnosed, and only one-seventh of American women with osteoporosis receive treatment.
- By the year 2050, the number of people beyond age 65 years in the United States will increase from 32 million to 69 million, and more than 15 million people will exceed 85 years of age. The incidence of hip and spine fractures increases with advancing age.
- The national health-care cost of osteoporosis was estimated to be $13.8 billion in 1995 and may increase to as much as $240 billion during the next 50 years.

PATHOGENESIS

Bone mass increases during the first 3 decades of life; it approaches maximal (peak) levels in the late teen years, increases slightly during the third decade of life, and reaches its peak around age 30 years (Fig. 2). Peak bone mass is primarily determined by genetics but may also be modified by other factors such as physical activity, diet (for example, inadequate calcium intake), concomitant diseases (such as hyperthyroidism), and adverse lifestyle practices (such as smoking). The level of peak bone mass achieved at skeletal maturity is a major determinant of bone mass in later life and is therefore a factor in the ultimate development of osteoporosis.

At menopause, bone remodeling becomes unbalanced and results in bone loss at each remodeling site. In addition, an increase in number of remodeling (that is, bone turnover) sites results in an accelerated bone loss throughout the entire skeleton. Postmenopausal bone loss is most rapid during the first postmenopausal decade (Fig. 2). Certain nutritional and lifestyle factors (such as insufficient dietary calcium or cigarette smoking) or the presence of concurrent disease (such as hyperthyroidism) may accelerate bone loss independent of the effects of declining estrogen concentration; thus, the risk of postmenopausal osteoporosis can be further increased. The remodeling space, which represents skeletal tissue that is undergoing remodeling and is therefore structurally ineffective, can be extended (worsened) by further increases in bone turnover or recovered by therapeutic agents that reduce bone turnover.

</tbody>
</table>

*BMD = bone mineral density; SD = standard deviation.
Bone loss due to estrogen deficiency and advancing age affects the entire skeleton. In the early postmenopausal years, bone loss averages 1 to 2% per year. Because the rate of remodeling is greater in cancellous bone than in cortical bone, however, bone loss attributable to estrogen deficiency and aging may be more rapid and manifest earlier at predominantly cancellous skeletal sites such as the lumbar spine.

CLINICAL FEATURES AND COMPLICATIONS

Low Bone Mass

Low bone mass is a major, consistent characteristic of postmenopausal osteoporosis. A strong inverse relationship exists between bone mass and susceptibility to fracture. Therefore, bone mass is the primary indicator of fracture risk in women without fractures, although it is important to realize that individual patients may sustain a fracture at different BMD levels and that factors other than bone density influence fracture risk (see BMD Measurement). In itself, low bone mass is not associated with symptoms.

Fracture

Fracture is the single morbid event and the most clinically significant physical manifestation of postmenopausal osteoporosis. Osteoporosis-associated fractures may occur in any bone but are most likely to occur at sites of low bone mass and are usually precipitated by a fall or injury. A fragility fracture results from trauma that would not cause a normal bone to fracture or from a force equal to or less than that resulting from a fall from standing height.

Hip fractures are the most serious complication of osteoporosis:

- They result in permanent disability in more than 30% of patients.
• Of patients with hip fracture, 12 to 20% die within 1 year after fracture.
• More than 50% of the survivors are unable to return to independent living; many require long-term nursing home care.

The following factors are important secondary complications of fractures:
• Pain
• Deformity
• Disability
• Physical deconditioning due to inactivity
• Changes in self-image

Adverse effects specific to spinal (vertebral) compression fractures include the following:
• Loss of height
• Kyphosis (dowager’s hump)
• Crowding of internal organs
• Back pain (acute and chronic)
• Prolonged disability
• Increased mortality

**RISK FACTOR ASSESSMENT**

**Risk Factors for Low Bone Mass**
“Risk factors” for low bone mass are not sufficiently sensitive for diagnosis or exclusion of osteoporosis. Only BMD measurements can identify patients who have low bone mass.

**Risk Factors for Fractures**
Assessment of risk factors for fractures may be useful for the following:
• Identifying women at high risk of fractures
• Heightening clinical awareness of osteoporosis
• Developing societal strategies for prevention of fracture and treatment of osteoporosis

The most important risk factors for osteoporosis-related fractures are as follows:
• Prior low-trauma fracture as an adult
• Low BMD in patients with or without fractures

A low-trauma fracture as an adult (40 to 45 years of age or older) is of major importance because it establishes an unusual susceptibility to fractures and strongly predicts the potential for future fractures. Therefore, it is a clear indication for further evaluation and possible therapeutic intervention.

Other factors are associated with an increased risk of hip fractures, but no available data confirm that they also influence the risk of other fractures. Although their clinical significance is not fully understood, they may be valuable for determining a strategy for prevention and treatment. These risk factors include the following:
• History of hip fracture in a first-degree relative
• Weight loss and low body weight
• Cigarette smoking
• Increased likelihood of falling
• Tallness
• High bone turnover
• Advancing age

Because more than one-third of women with osteoporosis have a coexisting cause of bone loss (Table 2), the fracture risk profile must consider secondary causes of osteoporosis (see Medical Evaluation).

**Risk of Falling**
Falls pose substantial problems for patients at high risk for fracture. The following factors are some common causes of falling:
• Frailty and associated deconditioning
• Poor visual acuity
• Impaired hearing
• Use of medications with neurologic effects that compromise protective neuromuscular reflexes (for example, long-acting benzodiazepines)

**EVALUATION**

The following patients should undergo assessment for postmenopausal osteoporosis:
• All women 65 years old or older
• All adult women with a history of a fracture (or fractures) not caused by severe trauma (such as a motor vehicle accident)
• Younger postmenopausal women who have clinical risk factors for fractures (who have low body weight—that is, less than 57.6 kg [127 lb]—or a family history of spine or hip fracturing)

The evaluation should include the following items:
• A comprehensive medical examination
• Assessment of risk factors for fractures (see Risk Factors for Fractures)
• BMD measurements in younger postmenopausal women who have risk factors and in all women 65 years old or older
• Assessment of the patient’s reliability, understanding, and willingness to accept available interventions

**Medical Evaluation**
A comprehensive medical evaluation, including a complete history and physical examination, is indicated in all women with postmenopausal osteoporosis in order to
identify coexisting medical conditions that cause or contribute to bone loss.

The following laboratory tests should be considered for any woman who has osteoporosis. These tests will establish baseline conditions or definitively exclude secondary causes of osteoporosis, even in the absence of other clinical indications:

- Complete blood cell count
- Serum chemistry studies (especially calcium, phosphorus, total protein, albumin, liver enzymes, alkaline phosphatase, creatinine, and electrolytes)
- Urinary calcium excretion

If the medical history or physical findings suggest secondary causes of bone loss, additional laboratory evaluations are warranted and may include (but are not limited to) the following tests:

- Serum thyrotropin
- Erythrocyte sedimentation rate
- Serum parathyroid hormone concentration (for possible primary or secondary hyperparathyroidism)
- Serum 25-hydroxyvitamin D concentration
- Urinary free cortisol and other tests for suspected adrenal hypersecretion
- Acid-base studies
- Biochemical markers of bone turnover (for example, bone-specific alkaline phosphatase and urine or serum collagen cross-links)
- Serum tryptase, urine N-methylhistamine, or other tests for mastocytosis
- Serum or urine protein electrophoresis (or both)
- Bone marrow aspiration and biopsy to look for marrow-based diseases
- Undecalcified iliac bone biopsy with double tetracycline labeling (consider only when osteoporosis is diagnosed and the patient has no apparent cause for the condition, no response to therapy, or suspected osteomalacia or mastocytosis)

The causes of secondary osteoporosis in adults are listed in Table 2.

Standard Radiography

In patients with known or suspected vertebral fractures or with an explained loss of height, radiography of the thoracic and lumbar spine is indicated to identify and confirm the presence of those fractures. Radiographic studies are usually indicated to confirm the presence of fractures at other sites as well. The sensitivity and reliability of standard radiography to assess BMD are poor, and in the absence of vertebral fractures, this technique cannot be used to diagnose osteoporosis.

Biochemical Markers of Bone Turnover

Currently, the precise role of biochemical markers in the clinical management of osteoporosis has not been established. Several confounding issues must be resolved before a clear role for these measurements can be determined. Age, gender, menopausal status, meals, diurnal variation, and certain medications all influence resorption marker levels and can cause extreme variability. Moreover, a relationship has not been demonstrated between
changes in bone marker levels after treatment and reduced fracture risk. In addition, the relationship between changes in bone marker levels and bone balance is unclear. Nevertheless, biochemical markers of bone turnover may be useful for the following specific situations:

- Assessing fracture risk in elderly patients
- Assessing therapeutic responses to antiresorptive agents, such as estrogen and bisphosphonates
- Identifying patients with high bone turnover (to predict rapid bone loss)

**BMD Measurement**

In women who are at risk for postmenopausal osteoporosis, BMD measurement can accomplish the following:

- Establish the diagnosis of postmenopausal osteoporosis
- Determine fracture risk (for every 1-SD decrease in age-adjusted BMD, the relative risk \[RR\] of fracture increases 1.5- to 2.5-fold)
- Identify candidates for intervention
- Assess changes in bone mass over time in treated and untreated patients
- Enhance acceptance of and adherence to treatment

**Measurement Techniques**

Dual x-ray absorptiometry of the lumbar spine and proximal femur provides reproducible values at important sites of osteoporosis-associated fracture. These central sites are also more likely than peripheral sites to show a response to treatment and are preferred for baseline and serial measurements. The most reliable comparative results for serial measurements are obtained when the same instrument and, ideally, the same technologist are used.

For bone mass measurement, several other techniques (listed here alphabetically) are available:

- Quantitative computed tomography for measurement of both central and peripheral sites
- Quantitative ultrasonometry
- Radiographic absorptiometry
- Single-energy x-ray absorptiometry

The various BMD measurement techniques are outlined in Table 3.

**Measurement Sites**

Peripheral measurements can identify patients with low bone mass. \(T\)-scores from peripheral devices, however, are not as sensitive or specific as those from central devices, and the risk of future fracture depends on the skeletal site even when \(T\)-scores from different skeletal sites are identical. Work is currently under way to redefine the thresholds for peripheral devices and resolve these discrepancies. In the meantime, peripheral measurements should be limited to the assessment of fracture risk.

**Bone Density Reports**

Bone density data are reported as \(T\)-scores and \(Z\)-scores. \(T\)-scores represent the number of SDs from the normal young adult mean bone density values, whereas \(Z\)-scores represent the number of SDs from the normal mean value for age- and sex-matched control subjects. Results showing \(Z\)-scores of \(-2.0\) or lower may suggest a secondary cause of osteoporosis.

Bone density reports also include values for specific subregions within the proximal femur and for specific vertebrae. Diagnostic and therapeutic studies, cost analyses, and cost-effectiveness data, however, are based on total hip, femoral neck, or total lumbar spine measurements (or some combination of these measurements).

**Role in Clinical Decision Making**

A clinical diagnosis of osteoporosis can be made without BMD testing in women who have fragility fractures. Nevertheless, BMD measurement is advisable in these patients to establish a baseline for assessing the response to treatment and for quantifying fracture risk.

For women with no history of fragility fracture, the WHO definitions of osteopenia and osteoporosis (Table 1) represent BMD levels associated with a high risk of fracture, as determined from prospective trials. Cutoff values, however, cannot define a true “fracture threshold” or the naturally occurring limits of a disease process because osteoporosis exerts its pathologic effects over a continuum of bone density values.

It must also be recognized that factors other than bone density have an important role in the pathogenesis of fractures. The increases in bone density that result from therapeutic interventions are modest and explain less than 50% of the observed reductions in fracture rates. When BMD is used as a surrogate endpoint in therapeutic trials, the relationship between bone mass and fracture rate is highly variable and depends on the specific agent used. For example, the relationship is reasonably strong in bisphosphonate trials, weak in raloxifene trials, and absent in trials that have used high-dose sodium fluoride or calcitonin. Clearly, factors other than bone mass also contribute to fracturing.

Therefore, treatment decisions for individual patients with low BMD should be made after consideration of non-bone mass factors as well, including the following:

- Patient acceptance and understanding of the risks and benefits of the proposed treatment
- Age (fracture risk increases with advancing age independent of bone density)
- The patient’s usual activity level and its historical effect on skeletal injury
- Patient expectations and functional needs
- Health status (for example, menopausal status and comorbidities)
- Lifestyle (such as use of tobacco and alcohol or risk-taking behavior)
- Medications (for example, postmenopausal women taking more than 7.5 mg of prednisone or its equivalent for more than 3 weeks should be considered for a preventive strategy with use of a bisphosphonate; women taking levothyroxine require periodic thyrotropin determinations and modification of thyroid hormone dose to normalize serum thyrotropin, if necessary)

**Indications**

The cost-effectiveness of BMD testing and the benefits to society are controversial. Clinicians, politicians, patients, industrial interests, and third-party payers all have different perspectives on the indications for and timing of BMD measurements. The following are recommendations intended to reflect the most effective and efficient use of this technology within the context of the endocrine specialty practice.

BMD measurements should be performed in the following settings:

- For risk assessment in perimenopausal or postmenopausal women who have risk factors for fractures and are willing to consider available interventions
- In women who have x-ray findings that suggest osteoporosis
- In women beginning or receiving long-term glucocorticoid therapy or other drugs associated with bone loss
- In all adult women with symptomatic hyperparathyroidism or other diseases or nutritional conditions associated with bone loss in whom evidence of bone loss would result in adjustment of management
- For establishing skeletal stability and monitoring therapeutic response in women receiving treatment for osteoporosis (baseline measurements should be made before intervention)
- In all women 40 years old or older who have sustained a fracture
- In all women beyond 65 years of age

**PREVENTION OF OSTEOPOROSIS**

Effective preventive strategies that can be implemented during skeletal development (infancy and childhood) and in later life are needed to minimize the physical, social, and economic consequences of osteoporosis. The following are goals of prevention programs:

- Optimize skeletal development and maximize peak bone mass at skeletal maturity
- Prevent age-related and secondary causes of bone loss
- Preserve the structural integrity of the skeleton
- Prevent fractures

**General Principles**

The following general principles are applicable to all individuals, particularly children and adolescents:

- **Promote a diet with adequate calcium content.** Adequate calcium intake is a fundamental element of any osteoporosis prevention or treatment program. The recommended daily calcium intake for various populations is outlined in Table 4, and a guide to calcium-rich foods is provided in Table 5. Calcium supplementation should be prescribed whenever it is needed to achieve the recommended daily intake levels (see Pharmacologic Agents). Although many of the effects of supplemental calcium on the developing skeleton are incompletely understood, it is well recognized that supplemental calcium substantially increases bone mass in physically active children.

- **Encourage good general nutrition.**
- **Promote adequate vitamin D intake (at least 400 IU/day; as much as 800 IU/day in the elderly).** Vitamin D is not widely available in natural food sources. It is primarily found in fish oils (including cod liver oil), some vegetables, and fortified milk, cereals, and...
breads. Supplements of 400 IU daily should be prescribed for younger adults. Supplements of 800 IU daily should be prescribed for elderly patients (in whom vitamin D absorption may be reduced), malnourished patients, patients with intestinal malabsorption, and patients receiving long-term anticonvulsant or glucocorticoid therapy.

- **Advocate regular weight-bearing exercise.** Weight-bearing exercise enhances bone development in children and adolescents and may slow bone loss attributable to disuse in elderly persons. In addition, regular exercise promotes mobility, agility, and muscle strength, all of which may help prevent falls.
- **Strongly discourage use of tobacco.** Cigarette smokers tend to be thinner, undergo earlier menopause, have increased catabolism of endogenous estrogen, and experience more fractures.

### Additional Measures

Consider the following additional measures in specific circumstances:

- **Pharmacologic agents** (in addition to calcium and vitamin D) to prevent bone loss in perimenopausal and postmenopausal women at high risk of developing osteoporosis
- **A bisphosphonate** (alendronate or risedronate) for all adult women who will require more than 7.5 mg of prednisone or its equivalent for more than 3 weeks (see Pharmacologic Agents)
- **Periodic monitoring of thyroid function,** and adjustment of the dose of thyroid hormone to normalize serum thyrotropin concentrations in all women receiving thyroid hormone replacement therapy for nonmalignant conditions
- **Identification and treatment of children and adolescents with constitutional delay of growth and puberty** and other states or conditions that predispose to low peak bone mass and osteoporosis in later life

Additional measures, listed in Table 4, should be personalized to the needs of each patient.

### TREATMENT OF OSTEOPOROSIS

#### Goals

The following are goals of treatment of osteoporosis:

- Prevent fractures
- Stabilize or achieve an increase in bone mass
- Relieve symptoms of fractures and skeletal deformity
- Maximize physical function (for example, halt progressive deformity)

The ability to achieve these goals depends on the patient’s and the physician’s commitment to therapy and the potential for the chosen therapy to yield results.

#### Candidates for Treatment

The following women may benefit from pharmacologic treatment of osteoporosis:

1. Women with postmenopausal osteoporosis
   - Women with low-trauma fractures and low BMD
   - Women with BMD T-scores of −2.5 and below
2. Women with borderline-low BMD (e.g., T-scores of −1.5 and below) if risk factors are present
3. Women in whom nonpharmacologic preventive measures are ineffective (bone loss continues or low-trauma fractures occur)

Nonpharmacologic Measures

Nonpharmacologic measures were reviewed in the section on preventive strategies (see General Principles).

Pharmacologic Agents

AACE and the American College of Endocrinology recommend the following pharmacologic agents when pharmacotherapy is indicated:

- **First priority**: agents approved by the US Food and Drug Administration (FDA) for the prevention or treatment (or both) of osteoporosis
- **Second priority**: agents that are not approved by the FDA but for which level 1 or level 2 evidence of efficacy and safety is available (these agents are appropriate for patients who are unable to take approved agents or who have complex and extenuating medical problems that preclude the effective use of approved agents)

Agents approved by the FDA for prevention or treatment of osteoporosis include (listed alphabetically) bisphosphonates (alendronate, risedronate), calcitonin, estrogen, and raloxifene. These agents suppress bone resorption, improve bone density, and reduce the risk of fractures. Level 1 evidence of efficacy in reducing the risk of vertebral fractures is available for bisphosphonates, calcitonin, and raloxifene. Level 2 evidence of antifracture efficacy is available for estrogen. Only bisphosphonates have been shown to reduce the risk of hip and other nonvertebral fractures in prospective controlled trials (level 1 evidence).

*The bioavailability of calcium varies depending on the food source and overall diet. For example, increasing fiber intake has long been associated with negative calcium balance. In cereals, phytic acid is the main constituent of fiber that binds calcium and makes it unavailable for absorption. In contrast, calcium absorption from low-oxalate vegetables (for example, kale, broccoli, collard greens) is as good as it is from milk.

†All milks (skim, 1%, 2%, and whole) have the same calcium content.

‡Breads and cereals, unless fortified with calcium, are relatively low sources of calcium but still contribute substantially to calcium intake because these foods constitute such a large part of the diet.
Calcium and Vitamin D Supplementation

Role in Clinical Practice.—Adequate calcium and vitamin D intake is fundamental to all prevention and treatment programs for postmenopausal osteoporosis.

Available Forms and Recommended Dosing.—The available forms and recommended dosages of calcium supplements are outlined in Table 7. To minimize gastrointestinal side effects and enhance absorption, patients should take calcium in conjunction with food (with meals or a bedtime snack).

Efficacy.—Calcium (500 to 1,000 mg/day) and vitamin D (400 to 800 IU/day) supplementation can reduce the rate of bone loss in women who are more than 5 years postmenopausal. The fracture reduction efficacy of calcium and vitamin D supplementation has been demonstrated in women beyond 75 years of age.

Side Effects.—The most common side effects of calcium are intestinal gas and constipation. These problems occur most frequently with calcium carbonate and are less likely with calcium citrate. Hypercalcuiuria is unusual at dosages of less than 2 g/day.

Contraindications.—Contraindications to use of calcium supplements include hypercalciuria (urinary calcium excretion of more than 300 mg/24 h) that cannot be controlled with a thiazide.

Duration of Treatment.—Calcium and vitamin D supplementation can be administered safely to most women indefinitely.

Bisphosphonates: Alendronate

Role in Clinical Practice.—Alendronate, a nitrogen-containing bisphosphonate, is approved by the FDA for prevention of bone loss in recently menopausal women, treatment of established postmenopausal osteoporosis, and treatment of glucocorticoid-induced osteoporosis.

Available Forms and Recommended Dosing.—The approved dosage of alendronate for prevention of bone loss in recently menopausal women and for treatment of corticosteroid-induced osteoporosis in men and estrogen-replete women is 5 mg daily (or 35 mg once weekly). For treatment of established postmenopausal osteoporosis and for treatment of corticosteroid-induced osteoporosis in estrogen-deficient women, 10 mg of alendronate daily (or 70 mg once weekly) is the approved dosage. Once-weekly dosing (that is, 70 mg once weekly) has been shown to be equivalent to daily dosing (10 mg/day), as reflected by changes in BMD and biochemical markers (level 2 evidence), but no fracture data are available.

Alendronate is supplied in 5- and 10-mg tablets for daily administration. It is also available in 35- and 70-mg tablets for once-weekly administration for prevention and treatment of postmenopausal osteoporosis, respectively. Alendronate should be taken with plain water on an empty stomach, at least 1½ hour before the first food, beverage, or orally administered medication of the day. Taking alendronate in conjunction with food, any beverage other than plain water, or certain medications, or ingesting it within 2 hours after a meal, may substantially reduce or abolish the absorption of alendronate. In order to avoid irritation of the esophagus, alendronate should be taken with approximately 8 ounces of water, and the patient should remain upright (seated or standing) until food has been eaten.

Efficacy.—Alendronate therapy has been shown in prospective, randomized, double-blind, placebo-controlled trials (level 2 evidence) to prevent bone loss and increase BMD at the spine and hip by 5 to 10%. Alendronate therapy has also been shown to prevent bone loss at the forearm and reduce the risk of fractures of the spine and nonvertebral sites such as the hip and wrist by 40 to 50% (level 1 evidence). The effects of alendronate on BMD at the spine and hip are maintained for at least 2 years after use of the drug is discontinued in older, but not in younger, patients (level 2 evidence). Alendronate has also been shown to be effective for the treatment of glucocorticoid-associated osteoporosis.

Side Effects.—Side effects of alendronate are generally mild and primarily affect the upper gastrointestinal system. In large-scale clinical trials, no apparent difference in tolerability has been noted between alendronate

and placebo. In clinical practice, however, upper gastrointestinal symptoms such as heartburn, indigestion, substernal discomfort, and pain with swallowing can occur, and rare instances of esophageal erosion, ulceration, or bleeding have been described. Serious problems have been reported in approximately 1 of 10,000 alendronate users and can often be explained by patient selection or dosing errors. The cause for upper gastrointestinal side effects is unclear. If side effects occur, use of alendronate should be discontinued until symptoms are resolved, after which a rechallenge should be considered.

Safety data for longer than 7 years of treatment are not available.

**Contraindications.**—Contraindications to alendronate therapy include hypersensitivity to alendronate, hypocalcemia, inability to follow the dosing regimen (that is, inability to remain upright for at least 1/2 hour), and presence of esophageal abnormalities that might delay transit of the tablet (for example, achalasia or stricture). Use of alendronate is relatively contraindicated in patients with active upper gastrointestinal disease. Hypocalcemia and other disturbances of mineral metabolism must be corrected before any bisphosphonate therapy is initiated. No dose adjustment of alendronate is necessary for patients who have mild to moderate renal insufficiency (creatinine clearance of 35 to 60 mL/min). Alendronate should be used with caution in patients who have more severe renal insufficiency.

**Duration of Treatment.**—The therapeutic efficacy of alendronate has been demonstrated for 7 years. Efficacy and safety beyond 7 years have not yet been established. When alendronate therapy is discontinued, no acceleration of bone loss relative to placebo has been noted, although slow bone loss may occur.

Bisphosphonates: Risedronate

Role in Clinical Practice.—Risedronate, a nitrogen-containing bisphosphonate, is approved by the FDA for prevention of bone loss in recently menopausal women, treatment of established osteoporosis, and prevention and treatment of glucocorticoid-induced osteoporosis in men and women.

Available Forms and Recommended Dosing.—Risedronate is supplied as 5- and 30-mg tablets. The approved dosage for prevention or treatment of osteoporosis is 5 mg daily. The use of once-weekly dosing for the treatment of osteoporosis is being investigated.

Risedronate should be taken with plain water on an empty stomach, at least 1/2 hour before the first food, beverage, or orally administered medication of the day. After taking risedronate, the patient should remain upright (seated or standing) until food has been eaten.

Efficacy.—Controlled clinical trial data show that risedronate increases BMD at the spine and hip, prevents bone loss at the forearm, and reduces the risk of fractures of the spine, hip, and other nonvertebral sites by 30 to 50% (level 1 evidence). Risedronate also preserves bone mass and reduces the incidence of vertebral fractures in glucocorticoid-treated patients.

Side Effects.—Adverse events associated with risedronate therapy in clinical trials did not differ from those associated with placebo. Whether the gastrointestinal tolerability of risedronate is different from that of alendronate is not known. Postmarketing experience suggests satisfactory tolerability. Safety data for longer than 3 years of treatment with risedronate are not available.

Contraindications.—Contraindications to risedronate therapy include hypocalcemia and hypersensitivity to risedronate. Hypocalcemia and other disturbances of mineral metabolism must be corrected before initiation of bisphosphonate therapy.

Duration of Treatment.—The therapeutic efficacy of risedronate has been demonstrated for a 3-year period. The efficacy and safety beyond 3 years have not yet been established, and the effect of termination of treatment on the rate of bone loss has not been assessed.

Other Bisphosphonates

Etidronate and pamidronate are available but have not been approved for prevention or treatment of osteoporosis. These agents are used "off label" for patients with osteoporosis.

- Etidronate has antifracture efficacy (level 1 evidence) and has been approved for treatment of osteoporosis in several countries. It is an alternative for patients who have gastrointestinal intolerance of approved orally administered bisphosphonates. Etidronate for treatment of osteoporosis is given in an intermittent cyclic regimen, 400 mg daily for 14 days, with cycles repeated every 3 months.
- Pamidronate, given by intravenous infusion, may be used for patients who cannot tolerate orally adminis-
tered bisphosphonates or who may not absorb orally taken bisphosphonates because of gastrointestinal disease (level 2 evidence). A typical treatment schedule for pamidronate is a loading dose of 90 mg followed by 30 mg every third month given by intravenous infusion in dextrose or saline during a 2-hour period.

Calcitonin

Role in Clinical Practice.—Injectable salmon calcitonin was approved by the FDA for treating osteoporosis in 1984. Its use was limited by the need for subcutaneous injection and side effects such as nausea and flushing that occurred in approximately 20% of subjects. Nasal spray salmon calcitonin has been available since 1995.

Available Forms and Recommended Dosing.—Injectable calcitonin is available in sterile solution. For maximal effect, 100 IU/day is administered subcutaneously or intramuscularly. Nasally administered calcitonin is available in a spray bottle that delivers 200 IU per puff. The recommended dosage is one spray (200 IU) daily.

Efficacy.—Several prospective, randomized, double-blind, placebo-controlled trials have shown modest increases in spinal BMD (level 2 evidence) with injectable calcitonin, but adequate trials to evaluate the effects of injectable calcitonin on fracture have not been conducted.

Nasal spray salmon calcitonin was approved by the FDA in 1995 for the treatment of postmenopausal osteoporosis, on the basis of preliminary data showing effects on BMD and an ongoing fracture trial. This 5-year trial, now completed, showed a 36% reduction in the incidence of new vertebral fractures with use of 200 IU of nasally administered calcitonin daily. Studies to assess the effect of calcitonin nasal spray on hip fractures or other nonvertebral fractures (level 1 evidence) have not been conducted.

Side Effects.—Common side effects of parenterally administered calcitonin, which occur in up to 20% of patients, include nausea, local inflammatory reactions at the injection site, and vascular symptoms, including generalized flushing and tingling of the hands.

The gastrointestinal side effects noted with parenterally administered calcitonin are rarely seen with the nasal spray. The major side effect of nasally administered calcitonin is nasal discomfort, including rhinitis, irritation of the nasal mucosa, and occasional epistaxis.

Contraindications.—The main contraindication to use of both forms of calcitonin is hypersensitivity. For patients with suspected sensitivity to the drug, skin testing is recommended before treatment.

Duration of Treatment.—The optimal duration of treatment with calcitonin (either the parenterally or the nasally administered form) is unknown.

Estrogen Replacement Therapy

Role in Clinical Practice.—In the United States, orally and transdermally administered forms of estrogen are approved for prevention of bone loss in recently menopausal women. A progestin should be administered concomitantly in women who have not undergone hysterectomy.
Available Forms and Recommended Dosing.—Continuous daily estrogen replacement therapy (ERT) is recommended to prevent estrogen-deficiency symptoms and to promote compliance. The available dosages of estrogens indicated for preventing or treating osteoporosis are outlined in Table 8.

For maximal skeletal protection, therapy with estrogen should begin at the time of menopause or oophorectomy. At any time after menopause, however, therapy can be initiated because correction of estrogen deficiency at any age prevents or slows bone loss in postmenopausal women with osteoporosis.

Efficacy.—Epidemiologic evidence and meta-analyses of pooled data (level 2 evidence) indicate that women exposed to ERT for more than 7 years have a 50% lower incidence of osteoporosis-related fractures than do nonusers. Prospective studies (level 2) have demonstrated increases in bone mass and reduced fracture rates over shorter periods of observation. Nevertheless, long-term estrogen users may still experience age-related bone loss, and continued ERT may be less likely to arrest bone loss or prevent fractures in women after age 75 years. A pooled estimate of the RR of hip fracture comparing estrogen users with nonusers is 0.7 (level 2 evidence).

Nonskeletal Effects.—Conjugated estrogen therapy is associated with a significant increase in serum high-density lipoprotein cholesterol levels and a reduction in serum concentrations of total cholesterol and low-density lipoprotein cholesterol. Similar changes also occur with continuous combined and cyclic conjugated estrogens/medroxyprogesterone acetate therapies.

Observational and retrospective studies suggest that the incidence of cardiovascular events and mortality associated with cardiovascular disease are one-third to one-half lower in women who receive ERT in comparison with those who do not (level 2 evidence). In contrast, however, a recent, large prospective secondary prevention trial showed that ERT was associated with no significant reductions in cardiovascular events in women with established coronary artery disease. Furthermore, women in this study who received ERT had more coronary artery disease events during the first year of therapy but fewer in years 4 and 5. AACE does not recommend prescribing estrogen for its putative cardioprotective effect until this question has been clarified by further studies.

Side Effects.—Women who have not undergone hysterectomy and who receive unopposed estrogen therapy have an increased possibility of developing endometrial neoplasia and malignancy. When appropriate dosages of progestin are added to the regimen, this risk diminishes and is comparable to that of women who are not taking hormone replacement therapy (HRT).

*Although some product labeling recommends cyclic therapy for osteoporosis, continuous administration is preferable for treatment of perimenopausal or postmenopausal women, to prevent cyclic recurrence of vasomotor symptoms.
†Combination conjugated estrogens/medroxyprogesterone acetate preparations (Prempro, Premphase) are also indicated for osteoporosis prevention.
Irregular vaginal bleeding can occur in women who have not undergone hysterectomy and who are taking a combined estrogen-progestin regimen. This risk diminishes with time, and up to 80% of women receiving a continuous combined regimen consisting of 0.625 mg of conjugated estrogens daily plus an appropriate dose of medroxyprogesterone acetate become amenorrheic within 1 year after initiation of treatment.

ERT increases the risk of cholelithiasis twofold. Moreover, fluid retention, mastalgia, abdominal pain, and headache may occur but may be ameliorated by use of a lower dose of estrogens.

In women who receive estrogen therapy in comparison with those who do not, the risk of venous thromboembolism is increased approximately threefold. The absolute risk is small (~3 in 1,000 to 3 in 10,000).

A small but significant increase in the RR of breast cancer is associated with use of ERT and HRT. Pooled estimates of RR range from 1.1 for only ERT to 1.4 when progestin is added. The risk increases with the duration of estrogen use (RR = 1 + 0.01 per year of use for ERT to 1 + 0.08 per year for HRT). Inconclusive evidence suggests that this risk is higher when cyclic HRT is taken for more than 4 years.

Contraindications.—The following factors are contraindications to estrogen or combination estrogen-progestin therapy:

- Known or suspected pregnancy
- Known or suspected cancer of the breast
- Known or suspected estrogen-dependent neoplasm
- Undiagnosed, abnormal genital bleeding
- Active thrombophlebitis or thromboembolic disorders or a history of thromboembolic disease
- Hypersensitivity to the hormones

Side effects not tolerated by the patient, as well as a substantial and uncontrollable increase in serum triglyceride levels, are valid reasons for discontinuing estrogen or estrogen-progestin therapy.

Duration of Treatment.—Estrogen therapy may be continued indefinitely. Direct evidence suggests that bone loss recurs after estrogen treatment is discontinued.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators activate estrogen receptors in target organs selectively to produce quantitatively variable estrogenic effects on estrogen-responsive tissues. Raloxifene has been approved by the FDA for prevention and treatment of postmenopausal osteoporosis. Raloxifene has agonistic effects on bone and lipoprotein production but has antagonistic effects on breast tissue and neutral effects on uterine mucosa.

Role in Clinical Practice.—Raloxifene is FDA approved for the treatment of postmenopausal osteoporosis and the prevention of bone loss in recently menopausal women.

Available Forms and Recommended Dosing.—

Raloxifene is available as a 60-mg tablet. The dosage of raloxifene for prevention of bone loss in recently menopausal women and for treatment of established osteoporosis is 60 mg daily.

Efficacy.—Among postmenopausal women with osteoporosis studied for 36 months, raloxifene (60 and 120 mg daily) reduced the risk of vertebral fractures by 30 to 50% (level 1 evidence). Raloxifene did not reduce nonvertebral fractures, but this study had insufficient statistical power for full assessment of the effects of this agent on nonvertebral fractures. Raloxifene increased BMD in the spine by 2.7% and in the femoral neck by 2.4% over placebo, and it reduced bone turnover to premenopausal levels.

Nonskeletal Effects.—Raloxifene reduces total cholesterol and low-density lipoprotein cholesterol fractions by about 7 and 11%, respectively, but it has no observable effect on concentrations of high-density lipoprotein cholesterol. The potential cardiovascular risks or benefits of raloxifene have not been studied.

In the Multiple Outcomes of Raloxifene Evaluation (MORE) Study of 5,129 postmenopausal women with osteoporosis treated with raloxifene, a 76% overall reduction of breast cancer and a 90% reduction in estrogen receptor-positive breast cancer were noted in comparison with placebo. A large study in patients at high risk for breast cancer is currently being conducted.

Side Effects.—As with estrogen, raloxifene is associated with an approximate threefold increase in venous thromboembolic diseases in comparison with placebo (RR 3.1), although the absolute risk is low. Other side effects include hot flashes, leg cramps, peripheral edema, and accumulation of endometrial fluid in the absence of endometrial disease.

Contraindications.—Raloxifene is contraindicated in women who are or are capable of becoming pregnant, who have had venous thromboembolic disease, or who are known to be hypersensitive to any component of raloxifene tablets.

Duration of Treatment.—Efficacy and safety have been determined for up to 40 months.

Concomitant Use of Therapeutic Agents

No data firmly establish that the combined use of two antiresorptive agents (for example, bisphosphonates plus ERT or raloxifene; estrogen plus calcitonin) has an additive effect on fracture reduction. Additive effects on bone mass and bone turnover have been observed. Until the effect of combined therapy on fracture risk is understood, however, AACE does not recommend concomitant use of these agents for prevention or treatment of postmenopausal osteoporosis.

Unapproved and Adjuvant Pharmaceutical Therapies

The unapproved and adjuvant therapies for postmenopausal osteoporosis are summarized in Table 9.
Follow-Up

The efficacy and safety of preventive and therapeutic strategies should periodically be reassessed, reinforced, and revised as needed. AACE recommends annual reassessment, which should include the following:

- Interim history
- Complete medical examination, including breast and pelvic examinations, mammography, and Papanicolaou smear if indicated
- Assessment of adherence to recommended program, including calcium, vitamin D, exercise, and any pharmacologic therapy
- Assessment of stature and skeletal integrity, including radiographic assessment of new deformities or newly symptomatic osseous deformities
- Reinforcement of the therapeutic program and evaluation of the patient’s level of understanding and concern
- Periodic assessment of BMD

BMD for Monitoring Treatment

Serial BMD measurements are useful for monitoring changes in bone mass. Each technique for evaluation of bone density has an inherent variability (that is, precision error) that must be considered when the clinical significance of BMD changes is assessed. With dual x-ray absorptiometry, for example, a BMD difference between measurements must be in the range of 3 to 5% to be clinically significant. Patients treated with bisphosphonates often demonstrate changes of this magnitude at the spine within a year and at the hip after 2 or more years. No change or even a slight reduction of BMD, however, is not evidence of treatment failure and does not warrant alteration of therapy.

Until specific data about the most efficient use of BMD for monitoring become available, the following general guidelines for performing follow-up BMD measurements may be used:

- For patients with “normal” baseline BMD (T-score more than −1.0), consider a follow-up measurement every 3 to 5 years. Patients whose bone density is well above the minimal acceptable level may not need further BMD testing.
- For patients in an osteoporosis prevention program, perform a follow-up measurement every 1 to 2 years until bone mass stability is documented. After BMD has stabilized, perform follow-up measurements every 2 to 3 years.
- For patients on a therapeutic program, perform a follow-up measurement yearly for 2 years. If bone mass has stabilized after 2 years, perform a follow-up measurement every 2 years. Otherwise, continue with annual follow-up measurements until stability of bone mass is achieved.

ACKNOWLEDGMENT

Wyeth-Ayerst Pharmaceuticals, Merck & Co., Inc., Procter & Gamble Pharmaceuticals, Inc., Novartis Pharmaceuticals Corp., and Eli Lilly and Company are gratefully acknowledged for providing financial support for publication of these guidelines. Herrin Communications, Brandamore, Pennsylvania, helped with preparation of the manuscript.
